Abstract

New-onset hyperglycemia in patients admitted to intensive care units increases the risk of morbidity and mortality. Insulin resistance is frequently seen in the treatment of stress-induced hyperglycemia. Metformin, an oral anti-hyperglycemic agent, may introduce a new treatment protocol in critically ill patients with insulin-resistance hyperglycemia.

Fifty-one non-diabetic traumatized patients with blood sugar (BS) levels more than 130 mg/dL were introduced to three days of treatment with intensive insulin (50 IU) or metformin (1000 mg, twice daily) therapy. Clinical evaluations included acute physiological and chronic health evaluation (APACHE II) and Glasgow Coma Scale (GCS). Experimental tests included BS level, mean arterial pressure (MAP), pH, HCO₃, and lactate.

Eight patients were excluded and 21 of remained patients treated with insulin and 23 with metformin. There was no significant difference in terms of the evaluated factors between the two groups at the time of admission. Although desirable BS level (BS < 130 mg/dL) was reached by three days of metformin treatment (p < 0.01), there was no significant difference in BS, MAP, pH and HCO₃ of insulin treated group in comparison with metformin treated patients. The findings were similar for APACHE II and GCS as well.

Although obvious studies are required, these findings may lead to effective therapies against stress-induced hyperglycemia.

Keywords: Metformin; Hyperglycemic; Ill patients; Insulin.

Introduction

There is a high risk of death and substantial morbidity in critically ill patients who require intensive care (1), because of increased susceptibility to severe infections and failure of

vital organs that amplify the risk of an adverse outcome (2). In these patients, as a normal response to stress, hyperglycemia is frequently seen. One third of all patients admitted to tertiary care centers have hyperglycemia, about 12% of whom have had no prior history of diabetes (3) that confirms the hyperglycemia of new onset in the general hospital wards (4) and intensive care units (5, 6).

Table 1. Data comparison between two groups of treatments before starting the insulin or metformin administration.

	Protocol A: Insulin treatment group	Protocol B: Metformin treatment group	p-value
Age	50 ± 21.68	48.4 ± 16.77	
BS (mg/dL)	149.25 ± 10.31	177.81 ± 20.17	0.32
MAP (mmHg)	94.7 ± 12.15	86.9 ± 7.14	0.07
HCO ₃ (mEq/L)	23.15 ± 2.30	23.80 ± 3.54	0.69
pH	7.42 ± 0.05	7.37 ± 0.11	0.15
APACHE II	23.25 ± 6.92	20 ± 6.32	0.42
G.C.S	9.5 ± 3.93	7.4 ± 3.78	0.20

Data are shown as mean ± SEM. All data have been taken before starting the treatment in both groups. $P < 0.05$ was assumed as statistical significance.

Since the traditional thought suggests hypoglycemia presents a more serious risk to critically ill patients than hyperglycemia really does, the treatment is often not initiated unless blood glucose exceeds 200 to 250 mg/dL (7, 8). Strict glucose control and safe implementation of normoglycemia in intensive care patients offers significant benefits for them (9, 10). Hyperglycemia in this population of patients derived from increased gluconeogenesis and insulin resistance (11, 12).

Insulin administration has been used in critically ill patients, other than hyperglycemic crises, to improve clinical outcomes (13). However, insulin resistance is a central feature of stress metabolism in postoperative patients, trauma patients, sepsis, and critical illness in general. In insulin resistance, glucose uptake is reduced in peripheral, insulin-sensitive tissues, whereas endogenous glucose production is increased, resulting in hyperglycemia (14).

Metformin was approved for patients with diabetes mellitus (15). It significantly accelerates glucose clearance, thereby attenuating hyperglycemia (16, 17). During hyperinsulinemia, glucose uptake was significantly greater in metformin-treated patients (18, 19). Patients receiving metformin also had a significantly higher plasma concentration of insulin (20, 21). As the existence of insulin resistance is suggested even in non-obese patients, for example with a BMI of 25 (22, 23), metformin therapy can be considered for the treatment of such patients as well (24). In case of critically ill patients, insulin resistance is seen along with hyperglycemia; therefore,

treatment with metformin may introduce new strategies in treatment of hyperglycemia and its adverse effects. The present study evaluates the consequence of metformin treatment in hyperglycemic critically ill patients.

Experimental

Study population

In this randomized clinical study, data was collected prospectively from non-diabetic traumatized patients admitted to the multi-disciplinary ICU of Sina Hospital (Tehran, Iran) with blood sugar levels more than 130 mg/dL. Between April 2006 and October 2007, fifty-one patients were eligible for enrollment in the study after their closest family members confirmed the written informed consent which they were given. Methods of data collection and analysis were approved by the research ethics committee of the hospital accredited by Ministry of Health and Medical Education of Iran. Eight patients were excluded in first 12 h of study due to the severe hemodynamical instability or signs of exclusion criteria including: age less than 18 or more than 75 years old, chronic renal failure (CRF, Creatinine > 1.2 mg/dL), bicarbonate < 13 mEq/lit, lactate > 4.5 mmol/lit, mean arterial pressure (MAP < 70 mmHg), creatinine clearance < 70 mL/min, pH < 7.3, and diabetic patients.

Study design

At the time of admission to the intensive care unit, included patients were randomly assigned to receive one of two protocols A or B for 72 h.

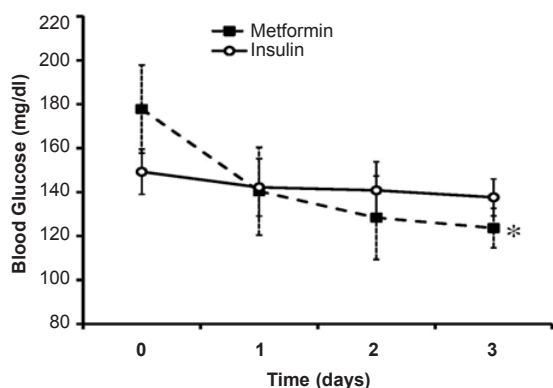

Figure 1. Effects of intensive insulin-therapy or metformin oral administration on blood sugar levels. Day 0 shows the BS levels before the beginning of each protocol. Data were expressed as mean \pm SEM. *: $p < 0.01$ in comparison with BS levels obtained before the onset of metformin treatment.

Figure 2. Mean arterial pressure (MAP) during three days of insulin or metformin treatment. Data were expressed as mean \pm SEM.

Then, patients received routine protocol.

Protocol A: Intensive insulin administration through intravenous injection

Fifty IU regular insulin (Exir Co., Tehran, Iran) was dissolved in 50 mL sodium chloride 0.9% solution. The amount of insulin infusion started in accordance with first blood sugar (BS) and then each 2 h BS was checked using glucometer (Roche ACCU-Check comfort or active system) to determine the required changes on insulin infusion.

Protocol B: Thousand mg of metformin (Exir Co., Tehran, Iran), twice daily through oral or NG tube administration

Only in the case of TPN, these patients received insulin in accordance with the amount of calories that had received. In this protocol, if the amount of BS in two subsequent evaluations was more than 300 mg/dL, that patient excluded from study. Serum lactate was checked (Roche Accutrend lactate system) per 6 h and metformin administration was stopped if serum lactate level was more than 4.5 mmol/L or if it was 2 mmol/L more than previous level, and also if $\text{HCO}_3^- < 13$ mEq/L or $\text{pH} < 7.35$ or serum creatinine remained above 1.2 mg/dL through two evaluations, and if $\text{MAP} < 70$ mmHg or urinary volume was less than 0.5 mL/Kg/min. All the excluded patients retained to ordinary protocol.

Measurement of APACHE II (acute physiological and chronic health evaluation) and GCS (glasgowcoma scale)

APACHE II which is one of the scoring systems in ICU units, measures the severity of disease in scales between 0 and 71, where increasing of score shows severity of disease and risk of death. APACHE II derives from twelve routine physiological assessments including blood pressure, temperature, heart rate and *etc.*

GCS is an observational method to assess the patient's consciousness in the base of neurologic scale from grade 3 (deep coma or death) to 15 (complete consciousness). GCS includes three tests of eye, speech and motor responses (25).

Statistical analysis

SPSS software (Statistical Product and Services Solutions, version 13.0, SPSS Inc, Chicago, IL, USA) was used to analyze the data. Statistical differences between groups were assessed using the Mann-Whitney test, and the t-test for continuous data. Values of $p > 0.05$ were considered statistically significant.

Results and Discussion

Twenty-one patients were treated with insulin as protocol A and 23 of them were introduced to protocol B (metformin treatment). Mean age of insulin and metformin-treated patients was 50 ± 21.68 and 48.4 ± 16.77 respectively.

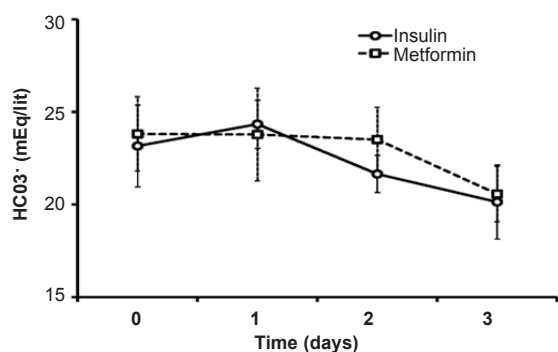

Figure 3. Changes on HCO₃⁻ serum during the treatment with insulin or metformin. Data were expressed as mean \pm SEM.

Initial experimental evaluations and clinical assessments were taken from patients of two groups in the admission period (Table 1). There was no significant difference between the first BS level of the admitted patients for the two different protocols ($p = 0.32$). Moreover, mean arterial pressure (MAP), serum HCO₃⁻ and pH levels were not statistically significant between the patients of two groups in admission ($p = 0.07$, 0.69 and 0.15 respectively, Table 1). In addition, APACHE II and G.C.S. have not showed significant difference for admitted patients of both groups in first day before the treatment. BS: Blood Sugar; MAP: Mean Arterial Pressure; APACHE II: Acute Physiological and Chronic Health Evaluation; G.C.S: Glasgow Coma Scale.

Blood sugar monitoring for three days of treatment

The mean levels of BS along three days of treatment were 140.19 ± 6.32 mg/dL in insulin-treated group and 130.77 ± 2.1 mg/dL in metformin-treated group. Although the mean level of BS in metformin-treated group was less than that of the other group, the difference was not significant (Figure 1). In insulin-treated group, the men's level of BS in the 1st day of admission was 149 mg/dL that reached to 137.61 mg/dL in the 3rd day of insulin treatment ($p = 0.15$). Metformin reduced BS from 177 mg/dL in the 1st day of admission to 123.63 mg/dL in the 3rd day of treatment ($p < 0.01$; Figure 1).

Desirable BS level ($80 \text{ mg/dL} < \text{BS} < 120 \text{ mg/dL}$) was not achieved through three days of insulin treatment (137.61 mg/dL) while it

reached near the normal range after three days of metformin treatment (123.63 mg/dL).

Effects of different protocols on MAP

As shown in Figure 3, there was no significant difference in MAP of patients treated with insulin compared to metformin-treated patients. During three days of insulin or metformin treatment, MAP was not changed significantly in comparison with the admitted values (Figure 2).

HCO₃⁻ and pH

Both pH and HCO₃⁻ did not change statistically during the insulin or metformin treatment. There is no significant difference between the mean levels of HCO₃⁻ in the mentioned groups during the treatment days or in each day of treatment (Figure 3). The mean pH level of metformin treated patients (7.38 ± 0.32) was less than that of insulin group (7.43 ± 0.29), which was not significant.

Serum's lactate in metformin-treated patients

Although in metformin-treated patients, the level of lactate at the end of procedure (2.22 ± 0.31) was less than that of the admitted point lactate value (2.87 ± 0.38), there were no significant changes in lactate values of metformin-related group during the study (Figure 5). (Figure 4).

Clinical assessments including APACHE II and G.C.S scale

Along three days of treatment, APACHE II did not change significantly in insulin-treated group or in patients treated with metformin. Although the level of APACHE II in protocol B patients was high than insulin-treated patients, the difference was not significant and after three days of treatment, the mean value of APACHE II was the same in both groups (22.25, Figure 6).

G.C.S value increased after three days of insulin or metformin treatment but there was no significant difference between them in both groups. The value of G.C.S during three days of insulin-treatment was more than the values on metformin-treated patients, but statistical analysis did not show any significant difference between the groups (Figure 7).

Hyperglycemia adversely affects the fluid

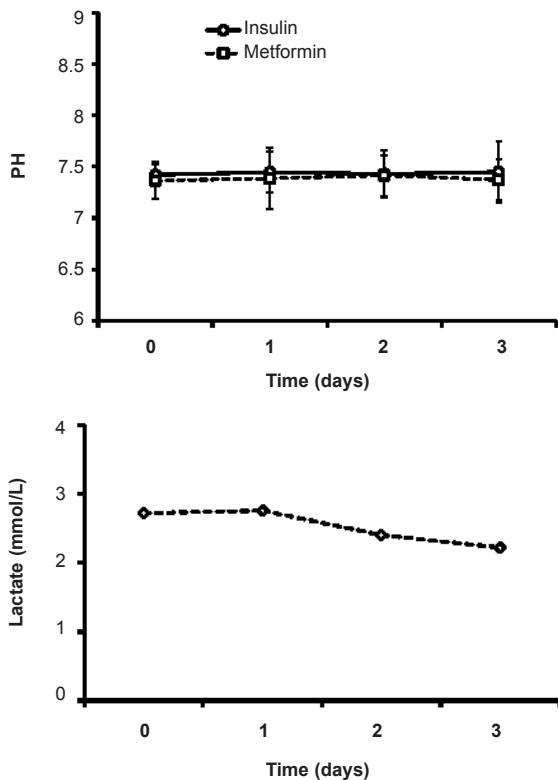

Figure 4. Effects of insulin or metformin treatment on the pH of serum. Data were expressed as mean \pm SEM.

balance, predisposes patient to infection, and increases the risk of renal failure, polyneuropathy and mortality in ICU (26). Although it has been reported that low dose metformin therapy improves the glycemic control in type 2 diabetic patients (24, 27), there has been no study so far comparing the effects of metformin therapy with that of insulin on hyperglycemia treatment in critically ill patients. The current study was aimed to compare the effects of metformin and intensive insulin administration on the hyperglycemia treatment in critically ill patients for the first time and showed that the metformin treatment reduces BS levels near to normal range. However, there was no difference in MAP, HCO_3^- and pH of insulin and metformin-treated patients. Both insulin and metformin treatments led to non-significant increase in GCS values and decrease in APACHE II.

A recent study on the comparison of metabolic effects of insulin and metformin on patients with severe burn injury greater than 40% of their body surface showed a significant anabolic

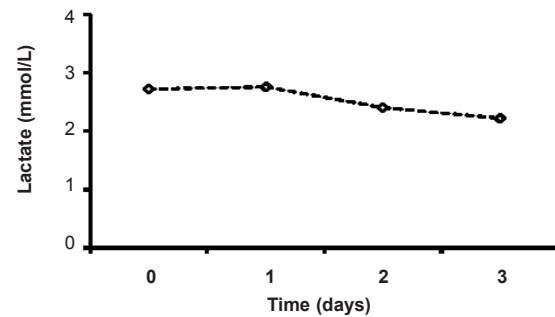

Figure 5. Serum lactate levels during three days of metformin treatment (1000 mg, twice daily).

effect on muscle protein with metformin and a modest response with insulin and suggested that metformin and insulin may work synergistically to further improve on muscle protein kinetics (28). In present study, metformin therapy reduced the BS levels but could not induce significant change on other evaluated parameters during the treatment period and results were the same as insulin.

It has been demonstrated that metformin reduces blood glucose levels predominantly through improving hepatic and peripheral tissue sensitivity to insulin without affecting the secretion of this hormone. It has been shown that metformin does not cause hypoglycemia (29). Metformin plus insulin appear to lower the incidence of insulin resistance and insulin requirement while maintaining blood glucose level control and consequently lower the incidence of adverse effects related to high-dose insulin therapy, particularly hypoglycemia in patients admitted to ICU (30, 31). In a study by Ansari *G. et al.*, patients with systemic inflammatory response syndrome (SIRS) and a blood glucose level of more than 120 mg/dL were admitted to an ICU received intensive insulin therapy or combination therapy with metformin and then blood samples were obtained at baseline and at 48 h, 96 h and 7 days after the initiation of study. The results of this study revealed that the addition of metformin to the insulin decreased insulin requirement and concentration of insulin and C-peptide, whereas decreased blood glucose level, therefore lowered the incidence of adverse effects related to the high-dose insulin therapy (31). A review of study (based on EMBASE and MEDLINE searches from January 1990 to

Figure 6. Evaluation of APACHE II (acute physiological and chronic health evaluation) as an index of severity of disease in scales between 0 and 71. Data were shown as mean±SEM during three days of insulin or metformin treatment and before the beginning of each treatment (Day 0).

Figure 7. Glasgow Coma Scale (G.C.S) used for assessing the patients' consciousness in scales between 3 (deep coma or death) to 15 (complete consciousness). Data were shown as mean±SEM before the beginning of each treatment (Day 0) and during three days of insulin or metformin treatment.

April 2006) done by Staels on two key classes of insulin-sensitizing agents—the biguanides (principally metformin) and thiazolidinediones (pioglitazone and rosiglitazone)—suggested that the thiazolidinediones and metformin, in spite of their distinct mechanisms of action, can provide the clinical opportunity for effective glucose control and metabolic risk reduction (31).

We did not use combination therapy of insulin and metformin since the aim of present study was the comparison of two different treatments separately and the results showed that when metformin is used as a single treatment, it can reduce the BS levels. To understand the precise effect of single metformin treatment on hyperglycemic patients in ICU, further studies on large ranges of samples and designing advanced protocols is needed.

Lactic acidosis caused by metformin is rare and the risk of this complication may be diminished by the observance of prescribing precautions and contraindications that avoid accumulation of metformin or lactate in the body (15). Lactate and pH levels did not change significantly during three days of treatment (Figures 4 and 5) which is a proof of the fact that metformin (1000 mg/day) cannot induce lactic acidosis.

In conclusion, compared to the intensive insulin therapy, metformin could not induce a significant change on the experimental parameters or conscious states of critically ill patients. Although metformin reduced BS levels to desired values along three days of treatment, further studies are needed to encompass

more patients or combination therapies with insulin or evaluation for a long time to disclose possible clinical insights on reducing the critically ill patients' mortality.
