Abstract

Aim

Patients with confirmed COVID-19 infection can develop several psychological consequences. Epidemiological data on mental health and psychological disorder inpatients infected with COVID-19 pneumonia are not available in Iranian patients. The purpose of this study was to evaluate the anxiety, stress, and depression of patients with COVID-19.

Material and Methods

This cross-sectional survey was conducted in 2020. All confirmed patients with COVID-19 were included in the study by census sampling. Assessment of depression, stress, and anxiety was performed using the DASS-21 questionnaire. All statistical analyses were performed using R version 3.5.1.

Results

The questionnaires were completed by 221 patients with COVID-19 infection (204 males,

17 females). The mean age was 45.90 ± 7.73 years. Our results indicated that the mean scores of depression and anxiety were at “extremely severe” levels, while stress levels were “severe.” The prevalence of “extremely severe” symptoms of depression and anxiety was 54.29% and 97.29%, respectively. The prevalence of severe stress was 46.61%.

Keywords Coronavirus 2019, COVID-19, patient, depression, anxiety, stress

Conclusion

In this study, patients infected with COVID-19 reported severe and extremely severe experience psychological distress. Further studies should focus on the combined use of psychological and molecular biomarker testing to increase accuracy. Overall, the findings demonstrate the necessity of special intervention programs for the confirmed patients with emerging infectious disease COVID-19 to promote mental health needs.

19.1 Introduction

Coronavirus disease 2019 (COVID-19) is mainly a respiratory system infection with a newly diagnosed coronavirus thought to have originated as a

zoonotic virus which has human pathogenicity [1]. The virus transmits from person to person through close contact or airborne probably as respiratory droplets [2]. At the time of writing (April 28, 2020), there have been approximately three million cases worldwide, with approximately 923,000 having recovered and 211,000 having died [3].

Therefore, virtually all patients with confirmed or suspected COVID-19 experience fear due to complications of the disease relating to the severe disability and potential death, in the absence of any definitive treatment or vaccine. In addition, symptoms such as fever, hypoxia, and cough, as well as adverse effects of treatment, could lead to worsening of anxiety and mental distress [4, 5]. In the early phases of the severe acute respiratory syndrome (SARS) and Middle East respiratory syndrome (MERS) outbreaks, a range of psychiatric morbidities, including persistent depression, anxiety, panic attack, psychomotor excitement, psychotic symptoms, delirium, and even suicidality, were reported [6, 7]. The persistence of depression in MERS survivors leads to prolonged chronic post-traumatic stress symptoms even 18 months after the infection [8]. A 14-day quarantine period and restrictions on social contact, which form part of the public health responses to the COVID-19 pandemic, could cause individuals to experience signs such as boredom, a higher level of depression, loneliness, and anger. It also could increase patients' guilt and anxiety about the effects of pathogenesis, quarantine, and stigma on their families and friends [4, 9]. Among the survivors of the SARS outbreak, stress levels were persistently elevated

97 1 year later, compared to people who were not
98 infected with SARS. SARS survivors had high
99 levels of psychological distress even 1 year after
100 the outbreak. This evidence suggests that the
101 long-term psychological implications of infec-
102 tious diseases should not be ignored and mental
103 health services could play an important role in
104 the rehabilitation of patients [6].

105 To date, epidemiological data on the mental
106 health of patients with COVID-19 in Iran has not
107 been established. The main purpose of this study
108 was to measure the prevalence and severity of
109 this psychological distress and gauge the current
110 mental health burden on patients with a diagnosis
111 of COVID-19 infection.

112 **19.2 Material and Methods**

113 **19.2.1 Study Design**

114 This cross-sectional survey was conducted in
115 February and March, 2020.

116 **19.2.2 Settings and Participants**

117 Baqiyatallah Hospital is one of the main refer-
118 ral centers for the specialized diagnosis and
119 treatment of patients with COVID-19 in Tehran,
120 Iran. Participants were recruited mainly as
121 patients referred to this hospital and patients
122 from other centers who gave consent to partici-
123 pate in the study. Other centers also participated
124 in this study, but since the number of partici-
125 pants from other centers was not high enough to
126 obtain a separate ethics code, the Dean of each
127 center approved data collection for their respec-
128 tive institutions. All patients over 18 years of
129 age who were interested in participating in this
130 study, who could read and write, with no preex-
131 isting physical disabilities or mental disorders,
132 were included. All participants were confirmed
133 COVID-19 positive. Census sampling was
134 used.

19.2.3 Sample Size

Cochran's sample size estimation formula in the
epidemiologic study was used [10]. The first
and second type errors were considered five-
hundredth and two-tenths, respectively. A 50%
satisfaction probability was assumed to estimate
the maximum sample size. The sample size was
calculated at 87 patients. According to the
nature of the study and the probability of sample
size drop, a 20% dropout was considered and
the final sample size was therefore calculated to
be 110.

19.2.4 Research Tools

Demographic characteristics were self-reported
by participants. These included sex, age, job,
marital status, educational qualification, and his-
tory of chronic disease. The Depression Anxiety
Stress Scale (DASS) was used to collect data.
This questionnaire was designed and validated by
Lovibond in 1995 [11] to measure psychological
distress among the community with 21 items.
This questionnaire included three subscales and
each subscale had seven questions. In the trans-
lated version, the choices were never, little, mod-
erate, and many for each question. The lowest
score for each question was 0 and the highest
score was 3. Validity and reliability of this ques-
tionnaire were previously established in Iran.
According to the original questionnaire, the three
subscales had high internal consistency with
Cronbach's alpha values of 0.77, 0.79, and 0.78
for depression, anxiety, and stress, respectively
[12]. Another study reported Cronbach's alpha
values greater than 0.80 for all scales in an analy-
sis of the effect of the 2008 Sichuan earthquake
in China [13].

The questions 3, 5, 10, 13, 16, 17, and 21 were
related to depression. Questions 1, 6, 8, 11, 12,
14, and 18 assessed stress. Q questions 2, 4, 7, 9,
15, 19, and 20 were related to anxiety. The cutoff
points of the subscales were as follows:

176 19.2.5 Depression Scores

- 177 0–4 = normal
 178 5–6 = mild
 179 7–10 = average
 180 11–13 = severe
 181 > 14 = very severe

182 19.2.6 Stress Scores

- 183 0–7 = normal
 184 8–9 = mild
 185 10–12 = average
 186 13–16 = severe
 187 >17 = very severe

188 19.2.7 Anxiety Scores

- 189 0–3 = normal
 190 4–5 = mild
 191 6–7 = average
 192 8–9 = severe
 193 >10 = very severe

194 19.2.8 Ethical Consideration

195 The study was approved by the Ethics Committee
 196 of Baqiyatallah University of Medical Sciences
 197 with code IR.BMSU.REC.1398,438. The objec-
 198 tives of the study were explained to all patients,
 199 and informed consent was obtained from the
 200 patients to participate in the study. They were
 201 also assured of confidentiality.

202 19.2.9 Statistical Analysis

203 All analyses were performed using R statistical
 204 software (version 3.5.1). The variables included
 205 gender (male, female), age (>30, 41–50,
 206 <40 years), marital status (married, unmarried),
 207 job (governmental, nongovernmental, unem-
 208 ployed, student, and housewife), background dis-
 209 ease (yes, no), and qualification (diploma or
 210 lower, associate, bachelor's degree, master's

degree, or higher). The values for each variable 211
 were presented as the mean and standard deviation. 212
 Independent samples *t*-test was applied as a 213
 parametric test to compare psychological symp- 214
 tom (stress, depression, and anxiety) scores by 215
 gender and marital status. One-way analysis of 216
 variance (ANOVA) test was applied to compare 217
 the mean differences in psychological factors in 218
 terms of age group, job, and educational qualifi- 219
 cation. A *p*-value of <0.05 was considered 220
 significant. 221

19.3 Results 222

The DASS-21 questionnaires were completed by 223
 221 patients with COVID-19 (204 males, 17 224
 females). The demographic characteristics are 225
 summarized in Table 19.1. The mean age was 226
 45.9 ± 7.73 years. A high proportion of patients 227
 reported a nongovernmental (37.1%) job. Most 228
 of the participants were unmarried (55.21%). In 229
 addition, 31.22% and 29.41% of the patients had 230
 “Bachelor” or “Associate” education level, 231
 respectively (Table 19.1). 232

The study results demonstrated that the compar- 233
 ison of mean scores for stress, depression, and 234
 anxiety subscales was not statistically significant 235
 in terms of “age,” “gender,” “job,” “marital sta- 236
 tus,” “background disease,” and “qualification” 237
 variables (Table 19.1). 238

Table 19.2 shows the prevalence and score 239
 severity ratings of psychological symptoms 240
 among patients with COVID-19 infection. Our 241
 results indicated that the mean scores of symp- 242
 toms of depression and anxiety were “extremely 243
 severe,” while stress was at “severe” levels. The 244
 prevalence of “extremely severe” symptoms of 245
 depression and anxiety was 54.29% and 97.29%, 246
 respectively. The prevalence of “severe” symp- 247
 tom of stress was 46.61%. 248

19.4 Discussion 249

The purpose of this study was to evaluate the 250
 anxiety, stress, and depression in hospitalized 251
 Iranian patients with confirmed COVID-19 infec- 252

Table 19.1 The mean (\pm SD) scores for psychological symptoms in terms of age group, gender, marital status, job, education level, and history of background disease (n = 221)

tion. This can serve as important evidence to manage the promotion of mental health among patients with COVID-19. The results of the current study indicated that the patients with confirmed COVID-19 revealed a high prevalence of symptoms associated with mental disorders. All of the patients reported varying levels of depression, anxiety, and stress. Extreme anxiety was found in 97.27% of patients and severe depression signs were reported by 54.29% of patients.

All patients who participated in the study had signs of stress. The prevalence of severe symptoms of stress was 46.61%. Similar results were found in 90% of SARS-infected patients. There was an increased prevalence of general stress and negative psychological effects in patients infected with SARS [14]. Another study reported that patients with MERS infection had an increased incidence of clinically relevant depressive and post-traumatic stress disorder (PTSD) symptoms [8]. Mac et al. reported that 44% and 47.8% of survivors of SARS suffered from respective depressive symptoms and PTSD after infection [15].

None of the demographic variables appeared to contribute to the mean scores of depression, anxiety, and stress. We did not observe any effect of age in our sample of patients. However, Yang et al. reported that older adults in crisis conditions could experience significantly more distress. Therefore, the older population may need relative more mental health intervention [16].

Stress levels were not related to educational qualifications indicating that patients with all levels of educational qualifications who are positive for COVID-19 were adversely affected.

There is growing evidence that in confirmed or suspected COVID-19 infection, patients will need more advanced mental healthcare [17]. Despite the mental health problems reported among patients with COVID-19, few of the healthcare workers on the frontlines had received training in providing mental healthcare [8, 18, 19]. For individuals with suspected or confirmed COVID-19 infection who are under treatment (quarantine or at home), health service personnel should provide medical care and mental healthcare [20]. Special attention needs to be paid for the behavioral and mood changes of these patients. Insomnia, anxiety, anger, rumination, decreased concentration, low mood, and loss of energy are listed as warning symptoms that should be evaluated and managed by mental healthcare professionals [17]. In view of this, there is an urgent need to develop and recommend online and on-site mental health interventions such as psychotherapy [21]. This should involve multidisciplinary mental health teams with expertise in specialized psychiatric treatments to provide appropriate mental health services during and after this COVID-19 epidemic with specific treatment plans, progress reports, and health status updates. There is a need to secure services to provide psychological

317 counseling in this group of patients. There should
 318 be more use of electronic devices and applica-
 319 tions for affected patients as well as their families
 320 and members of the public. There is also a need
 321 to establish safe communication channels
 322 between patients and families. To date, mental
 323 health interventions are only provided for those
 324 presenting with more severe mental health prob-
 325 lems [5]. Since personnel such as clinical psy-
 326 chiatrists, psychologists, and mental health social
 327 workers are unable to enter isolation wards for
 328 patients with COVID-19, frontline healthcare
 329 workers should be trained to provide psychologi-
 330 cal interventions for patients with COVID-19 in
 331 hospitals [20].

332 One of the limitations of this study was the
 333 single-center cross-sectional survey design
 334 which limits the generalizability of the findings.
 335 In addition, this study was conducted at the
 336 onset of the COVID-19 outbreak, and, there-
 337 fore, there might be further changes in the men-
 338 tal health status of these patients. Finally, we did
 339 not assess the risk factors that may have affected
 340 depression, anxiety, and stress in patients with
 341 COVID-19 infection, and the prior absence of
 342 mental disease in these patients was self-
 343 reported. Further studies should focus on the
 344 incorporation of molecular biomarkers into such
 345 tests to increase accuracy. Such biomarkers
 346 should be easily accessible for ease of sampling
 347 and to minimize patient discomfort. For exam-
 348 ple, this could include analysis of stress-related
 349 biomarkers such as cortisol and alpha-amylase
 350 A in saliva [22, 23] and proinflammatory cyto-
 351 kines such as tumor necrosis factor alpha and
 352 interleukin (IL)-1 and IL-6 in blood serum or
 353 plasma [24, 25].

354 19.5 Conclusions

355 In this study, patients infected with COVID-19
 356 reported severe and extremely severe psycho-
 357 logical distress. There is a need for introduction
 358 of the mental health interventions in this patient
 359 group. As the situation has now progressed to a
 360 pandemic, the effects on mental health could be
 361 even more profound. This is also complicated

by the risk of further outbreaks, the lack of treat- 362
 ments and a vaccine, as well as the effects on the 363
 economy at a global level. Given these chal- 364
 lenges, it will be important to incorporate the 365
 use of molecular biomarkers to increase the 366
 accuracy of assessing the dynamic changes in 367
 mental health during the evolution of the 368
 pandemic. 369
